Common work with: Sébastien Briaïs, Stéphane Caron,  
Jean-Luc Danger, Sylvain Guilley, Jacques-Henri Jourdan,  
Arthur Milchior, David Naccache, Thibault Porteboeuf

# NEEDS OF 3D INTEGRATION

- ▶ 3D integration is currently seen as the future of chip manufacturing.
- ▶ 3D integration opens new opportunities for implementing physical chip protections.
- ▶ In particular creating active shields for an entire chip stack, and not only the topmost die. Such shields might protect against a wider range of attacks than conventional active shields.

# STATE OF THE ART

ST Microelectronics active shield in ST16 smartcard:

- ▶ active shield pattern that carries supply voltage
- ▶ hacked without the use of FIB on  $0,18\mu$  technology

(Photo's courtesy of C.Tarnovsky)

Atmel active shield in a ATSHA 204 chip:

- ▶ full serpentine over the entire chip
- ▶ active shield patterns detects disconnections and short circuits
- ▶ no probe points or test pads

(Photo's courtesy of [www.digikey.com](http://www.digikey.com))

## OUR IDEA

- ▶ Build a Hamiltonian mesh to completely surround the protected chip.
- ▶ Cage spread on several metal layers and/or dies.
- ▶ Vertical connections are made using via.

# TOOLBOX FOR GENERATING HAMILTONIAN STRUCTURES

- ▶ We investigated several Hamiltonian path generators, using different approaches.
- ▶ Looking for a trade-off between computation time and randomness.
- ▶ Our algorithms can be extended to generate several interleaved Hamiltonian circuits.

## STRETCHING ALGORITHM

- ▶ This algorithm maintains and extends a set of edges in one of the four possible extension directions.
- ▶ If the algorithm doesn't find an available extension, then it resumes the search.
- ▶ The algorithm is very slow, 30 hours for generating a cube of size 8 on a server.

# SQUARE ASSOCIATION

- ▶ Two elementary squares can be associated in only two ways

- ▶ We map the plan with elementary squares and associate them randomly until one single Hamiltonian path is obtained

## MORE THAN ONE PATH

In the same way we can create several Hamiltonian paths interleaved on a unique metal layer in the interest of cost.

## FROM 2D TO 3D STRUCTURES

- ▶ We can now fold a planar structure as we would fold a sheet of paper.
- ▶ With a regular folding we obtain a predictable shape. However, more technical folding techniques result in more intricate 3D structures.

# RANDOMIZING

Folding a planar structure, even randomly, creates regular and hence predictable structures. We randomize the resulting structure using a 3D rewriting rule.

# CUBE ASSOCIATION

- ▶ There are six different elementary Hamiltonian cubes

- ▶ Fill the volume to cover with randomly picked elementary cubes

# SILICON EXPERIMENTS

We made a silicon prototype to illustrate the idea, a cage covering an 8-bit register. The cage stretches over six metal layers on a 130nm technology.

# INTEGRATION INTO DESIGN TOOLS

- ▶ Our prototype layout was “handmade”, this limited us to a certain size.
- ▶ Our lightweight algorithms can be integrated within a design environment to automate the active shield’s layout generation.
- ▶ The shield has to comply with manufacturing constraints regarding metal line spacing and minimal metal line width.

## FROM PASSIVE TO DYNAMIC SHIELDING

- ▶ If mesh geometries are predictable, attacks (strapping) become easier.
- ▶ Digital signal transmission provides a way of ensuring shield integrity.
- ▶ Re-routing **dynamically** a logic signal between switch-boxes allows the creating of a unique cryptographic response per configuration.
- ▶ Our shield purpose is to warn the protected circuit of any attack, in same way canaries were used in coal mines to detect poisonous gazes.

## THE CANARY SWITCH-BOXES

- ▶ A network made of substrate-level switch-boxes forming a cage surrounding the protected chip.
- ▶ Each switch-box has programmable routing and cryptographic capabilities that make the network dynamic.
- ▶ The network acts as a verification circuit creating different cryptographic responses for different inputs.

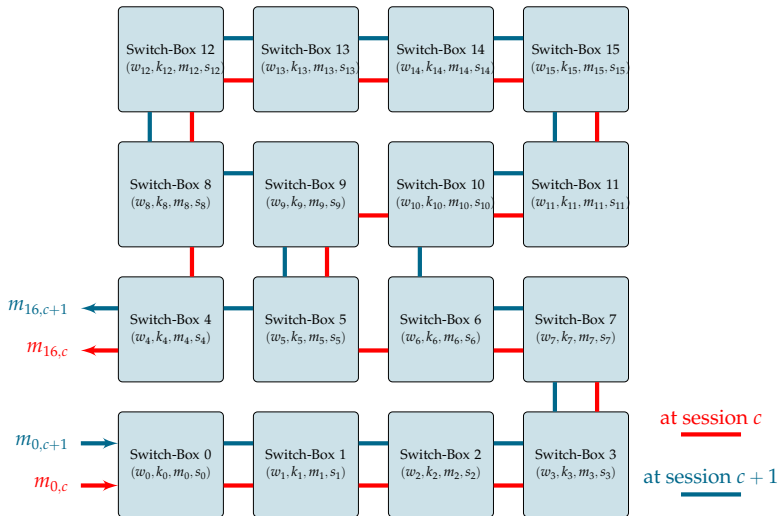

# SWITCH-BOX FUNCTIONS

- ▶ Several cell-level parameters are used to define each switch-box: A coordinate identifier  $i$ , a session identifier  $c$ , a key  $k_i$ , a routing configuration  $w_i$  and a state variable  $s_{i,c}$ , computed and stored at each clock cycle from the incoming data  $m_{i,c}$  and the preceding state  $s_{i,c-1}$ .

$$\begin{cases} m_{i+1,c} & = & F(m_{i,c}, k_i, w_{i,c}, s_{i,c}) \\ s_{i,c+1} & = & G(m_{i,c}, k_i, w_{i,c}, s_{i,c}) \end{cases}$$

- ▶ The output data  $m_{i+1,c}$  is computed by box  $i$  using the input data  $m_{i,c}$  and an integrated cryptographic function  $F$ , serving as a lightweight MAC.

$$m_{16,c} \neq m_{16,c+1}$$

# DYNAMIC ACTIVE SHIELD

- ▶ Each node represents a switch Box
- ▶ Each network configuration gives a different datapath defining a different mathematical function.

# MIRROR VERIFICATION CIRCUIT

- ▶ Our “hardware canary” is formed by a spatially distributed chain of functions  $F_i$  positioned at the vertices of a 3D cage surrounding a protected circuit.
- ▶ In essence, a correct answer  $(F_n \circ \dots \circ F_1)(m)$  to a challenge  $m$  will attest the canary’s integrity.

# POSSIBLE EMBODIMENT

- ▶ Switch-boxes can spread over several dies.
- ▶ The number of switch-boxes doesn't have to be very big.

# CONCLUSIONS

- ▶ The proposed dynamic active shield can be built using a small number of switch-boxes.
- ▶ The main limitation is the number of layers used for the shield to keep manufacturing costs reasonable along with the design rules that have to be followed.
- ▶ Timing can be an issue for LSI as well as the power needed to drive signals through long serpentine (cf FDTC'12 "Random active shield").
