**Abstract.** In this talk we will illustrate the everyday challenges met by embedded security practitioners by five real examples. All the examples were actually encountered while designing, developing or evaluating commercial products.

This note, which is  $\underline{not}$  a refereed research paper, presents the details of one of these five examples. It is intended to help the audience follow that part of our presentation.

## 1 Foreword

When I was asked to give this talk, I was delighted, but a bit concerned.

What in my brief decade in the card industry would be of interest to a group of practitioners far more experienced in security than myself?

What will my story be?

As I started to question ex-colleagues, competitors and suppliers, I quickly realized that the problem would be in deciding what to leave out rather than what to include. I was finally able to narrow my list to five examples.

The first ones will deal with an electronic circuit that mysteriously vanished into thin air, DES and RSA key-management in early-generation cards, a cryptographic watchdog chasing own tail and the story of the industry's first on-board sensors.

This note, which is <u>not</u> a referred paper, presents the details of the fifth example – coauthored with one of my students. It is intended to help the audience follow that part of the talk – a talk that I dedicate to the memory of our friends and colleagues Prof. Dr. Thomas Beth (1949–2005) and Prof. Dr. Hans Dobbertin, (1952–2006).

David Naccache

### 2 Introduction

Aliens are a fictional bloodthirsty species from deep space that reproduce as parasites. Aliens lay eggs that release araneomorph creatures (facehuggers) when a potential host comes near. The facehugger slides a tubular organ down the victim's throat, implanting a larva in the victim's stomach.

Within a matter of hours the larva evolves into a chestburster and emerges, violently killing the host; chestbursters develop quickly and the cycle restarts.

Just as Aliens, rootkits, worms, trojans and viruses penetrate healthy systems and, once in, alter the host's phenotype or destroy its contents. Put differently, malware covertly inhabits *seemingly normal* systems until something triggers their awakening.

As illustrated recently [4], detecting new malware species may be a nontrivial task. In theory, the easiest way to exterminate malware is a disk reformat followed by an OS reinstallation from a trusted distribution CD. This relies on the assumption that computers can be *forced* to boot from trusted media.

However, most modern PCs have a flash BIOS. This means that the codecomponent in charge of booting has been recorded on a rewritable memory chip that can be updated by specific programs called *flashers* or, sometimes, by malware such as the CIH (Tchernobyl) virus.

Hence, a natural question arises:

How can we ascertain that malware did not re-flash the BIOS to derail disk reformatting attempts and simulate their successful completion?

Flash smart cards<sup>1</sup> are equally problematic. Consider a SIM-card produced by Alice and sold empty to Bob. Bob keys the card. Alice reveals an OS code but flashes a malware simulating the legitimate OS. When some trigger-event occurs<sup>2</sup> the malware responds (to Alice) by revealing Bob's keys.

This note describes methods allowing Bob to check that SIMs bought from Alice contain no malware. Bob's only assumption is that his knowledge of the device's *hardware* specifications is correct.

In biology, the term *Alien* refers to organisms introduced into a foreign locale. Alien species usually wreak havoc on their new ecosystems – where they have no natural predators. In many cases, humans deliberately introduce matching predators to eradicate the alien species. This is the approach taken here.

**Related topic:** What we try to achieve differs fundamentally from program competitions for the control of a virtual computer, such as Core War. Here the verifier *cannot see* what happens inside a device and seeks to infer the machine's state given its behavior.

<sup>&</sup>lt;sup>1</sup> e.g. SST Emosyn, Atmel AT90SC3232, Infineon SLE88CFX4000P, Electronic Marin's EMTCG, etc.

 $<sup>^2\,</sup>e.g.$  a specific 128-bit challenge value sent during the GSM authentication protocol.

### 3 The Arena

We tested the approach on Motorola's 68HC05, a very common eight-bit microcontroller (more than five billion units sold). The chip's specifications were very slightly modified to better reflect the behavior of a miniature PC.

The 68HC05 has an accumulator A, an index register X, a program counter PC (pointing to the memory instruction being executed), a carry flag C and a zero flag Z indicating if the last operation resulted in a zero or not. We denote by  $\zeta(x)$  a function returning one if x = 0 and zero otherwise (e.g.  $\zeta(x) = \lfloor 2^{-x} \rfloor$ ).

The platform has  $\ell \leq 2^{16} = 65536$  memory bytes denoted  $M[0], \ldots, M[\ell - 1]$ . Any address  $a \geq \ell$  is interpreted as  $a \mod \ell$ . We model the memory as a state machine insensitive to power-off. This means that upon shut-down, execution halts and the machine's RAM is backed-up in non-volatile memory. Reboot restores RAM, resets A, X, C and Z and launches execution at address 0x0002 (which *alias* is start).

The very first RAM state (digital *genotype*) is recorded by the manufacturer in the non-volatile memory. Then the device starts evolving and modifies its code and data as it interacts with the external world.

The machine has two I/O ports (bytes) denoted In and Out. Reading In allows a program to receive data from outside while assigning a value to Out displays this value outside the machine. In and Out are located at memory cells M[0] and M[1] respectively. Out's value is restored upon reboot (In isn't). If the device attempts to write into In, execute In or execute Out, execution halts.

The (potentially infested) system pretends to implement an OS function named Install(p). When given a string p, Install(p) installs p at start. We do not exclude the possibility that Install might be modified, mimicked or spied by malware. Given that the next reboot will grant p complete control over the chip, Install would typically require some cryptographic proof before installing p.

EFFECT	lda i	sta i	bne k	bra $k$

### 4 Quines as Malware Predators

A Quine (named after the logician Willard van Orman Quine) is a program that prints a copy of its own code [1, 2]. Writing Quines is a tricky programming exercise yielding Lisp, C or natural language examples such as:

```
((lambda (x) (list x (list (quote quote) x)))
 (quote (lambda (x) (list x (list (quote quote) x))))
char *f="char*f=%c%s%c;main(){printf(f,34,f,34,10);}%c";
main() {printf(f,34,f,34,10);}
```

Copy the next sentence twice. Copy the next sentence twice.

We start by loading a Quine into the tested computer. The device might be under the malware's total spell. The malware might hence neutralize the Quine or even analyze it and mutate (adapt its own code in an attempt to fool the verifier). As download ends, we start a protocol, called *phenotyping*, with whatever survived inside the platform. Phenotyping will allow us to prove (Section 5) or assess the conjecture (Section 4) that the Quine survived and is now in full control of the platform. If the Quine survived we use it to reinstall the OS and eliminate itself; otherwise we know that the platform is infected. As we make no assumptions on the malware's malefic abilities, there exist extreme situations where decontamination by software is impossible. A trivial case is a malware controlling the I/O port and not letting anything new in. Under such extreme circumstances the algorithms presented in this note will only detect the malware but will be of no avail to eliminate it.

The underlying idea is that, upon activation, the Quine will (allegedly!) start dumping-out its own code plus whatever else found on board. We then *prove* or conjecture that the *unique* program capable of such a behavior, under specific complexity constraints, is *only* the Quine itself.

In several aspects, the setting is analogous to the scenario of *Alien vs. Preda*tor, where a group of humans (OS and legitimate applications) finds itself in the middle of a brutal war between two alien species (malware, Quine) in a confined environment (68HC05).

### 5 Space-Constrained Quines

We start by analyzing the simple Quine given below (Quine1.asm). This 19byte program inspects  $\ell = 256$  bytes platforms. Quine1 is divided into three functional blocks separated by artificial horizontal lines. First, a primitive command dispatcher reads a byte from In and determines if the verifier wants to read the device's contents (In = 0) or write a byte into the RAM (In  $\neq 0$ ).

As the program enters **print** the index register is null. **print** is a simple loop causing 256 bytes to be sent out of the device. As the loop ends, the device re-jumps to **start** to interpret a new command.

The store block queries a byte from the verifier, stores it in M[X] and rejumps to start.

start:	ldx	In	;	X←In	0xBE	0x00
	bne	store	;	if X $ eq$ 0 goto store	0x26	0x09
print:	lda	M,X	;	A←M[X]	0xE6	0x00
	sta	Out	;	Out←A	0xB7	0x01
	incx		;	Х++	0x5C	
	bne	print	;	if X $ eq$ 0 goto print	0x26	0xF9
	bra	start	;	if X=0 goto start	0x20	0xF3
store:	lda	In	;	A←In	0xB6	0x00
	sta	M,X	;	$A \longrightarrow [X] M$	0xE7	0x00
	bra	start	;	goto start	0x20	OxED

The associated phenotyping  $\phi_1$  is the following:

- 1. Install(Quine1.asm) and reboot.
- 2. Feed Quine1 with 235 random bytes to be stored at M[21],...,M[255].
- 3. Activate print (command zero) and compare the observed output to:

$$s_1 = 0x00 0x00 0xBE 0x00 0x26 0x09 0xE6 0x00 0xB7 0x01 0x5C 0x26 0xF9 0x20 0xF3 0xB6 0x00 0xE7 0x00 0x20 0xED M[21],...,M[255]$$

Is Quine1.asm the only nineteen-byte program capable of always printing  $s_1$  when subject to  $\phi_1$ ?

We conjecture so although (unlike the variant presented in the next section) we are unable to provide a formal proof. To illustrate the difficulty, consider a *slight* variant:

start:	ldx	In	;	X←In	0xBE	0x00
	bne	store	;	if X $ eq$ 0 goto store	0x26	0x0B
label:	tst	label	;		0x3D	0x06
print:	lda	M,X	;	[X]M→A	0xE6	0x00
	:	:	;	same code as in Quine1		

For all practical purposes, this modification  $(\texttt{Quine2.asm})^4$  has nearly no effect on the program's behavior: instead of printing  $s_1$ , this code will print:

$$\begin{split} s_2 = 0 \texttt{x00} \ 0 \texttt{x00} \ 0 \texttt{xBE} \ 0 \texttt{x00} \ 0 \texttt{x26} \ 0 \texttt{x0B} \ 0 \texttt{x3D} \ 0 \texttt{x06} \ 0 \texttt{xE6} \ 0 \texttt{x00} \\ 0 \texttt{xB7} \ 0 \texttt{x01} \ 0 \texttt{x5C} \ 0 \texttt{x26} \ 0 \texttt{xF9} \ 0 \texttt{x20} \ 0 \texttt{xF1} \ 0 \texttt{xB6} \ 0 \texttt{x00} \ 0 \texttt{xE7} \\ 0 \texttt{x00} \ 0 \texttt{x20} \ 0 \texttt{xEB} \ \texttt{M}[23], \dots, \texttt{M}[255] \end{split}$$

Let Quine3 be Quine2 where tst is replaced by inc.

When executed, inc will increment the memory cell at address label which is *precisely* inc's own opcode. But since inc's opcode is 0x3C, execution will transform 0x3C into 0x3D which is... the opcode of tst.

All in all,  $\phi_2$  does not allow to distinguish a tst from an inc present at label, as both Quine2 be Quine3 will output  $s_2$ .

The subtlety of this example shows that a microprocessor-Quine-phenotyping triple  $\{\mu, Q, \phi\}$  rigorously defines a problem:

Given a state machine  $\mu$  find a state M (malware) that simulates the behavior of a state Q (legitimate os) when  $\mu$  is subject to stimulus  $\phi$  (phenotyping).

<sup>&</sup>lt;sup>4</sup>  $\phi_1$  should be slightly twitched as well (233 random values to write).

Security practitioners can proceed by analogy to the assessment of cryptosystems which specifications are published and submitted to public scrutiny. If an M simulating Q with respect to  $\phi$  is found, a fix can either replace Q or  $\phi$  or both. Note the analogy: Given a stream-cipher  $\mu$  and a key Q (defining an observed cipher-steam  $\phi$ ), prove that the key Q has no equivalent-keys M.

An alternative solution, described in the next section, consists in proving the Quine's behavior under the assumption that the verifier is allowed to count clock cycles (state transitions if  $\mu$  is a Turing Machine).

#### 6 Time-Constrained Quines

Consider the following program loaded at address start:

start:	ldx	In	;	3	cycles;	X←In		(instruction	$I_1)$
	stx	Out	;	4	cycles;	Out←X	Ι	(instruction	$I_2$ )
	÷	:	;		;	other	instructions		

Latch a first value  $v_1$  at In and reboot, as seven cycles elapse  $v_1$  pops-up at Out. If we power-off the device before the eighth cycle and reboot,  $v_1$  reappears on Out<sup>5</sup> immediately. Repeating the process with values  $v_2$  and  $v_3$ , we witness two seven-cycle transitions  $v_1 \rightsquigarrow v_2$  and  $v_2 \rightsquigarrow v_3$ .

It is impossible to modify two memory cells in seven cycles as all instructions capable of modifying a memory cell require at least four cycles. Hence we are assured that between successive reboots, the *only* memory changes are in Out. This means that no matter what the examined code is, this code has no time to mutate in seven cycles and necessarily remains invariant between reboots.

The instructions other than sta and stx capable of modifying directly Out are: ror, rol, neg, lsr, lsl, asl, asr, bset, bclr, clr, com, dec and inc. Hence, it suffices to select  $v_2 \neq \operatorname{dir}(v_1)$  and  $v_3 \neq \operatorname{dir}(v_2)$ , where dir stands for any of the previous instructions<sup>6</sup>, to ascertain that Out is being modified by an sta or an stx (we also need  $v_1 \neq v_2 \neq v_3$  to actually see the transition).

 $v_1 = 0x04, v_2 = 0x07, v_3 = 0x10$  satisfy these constraints.

As reading or computing with a memory cell takes at least three cycles there are only four cycles left to alter the contents of Out; consequently, the only sta and stx instructions capable of causing the transitions fast enough are:

 $<sup>^{5}</sup>$  Out being a memory cell, its value is backed-up upon power-off.

<sup>&</sup>lt;sup>6</sup> for ror and rol, consider the two sub-cases C = 0 and C = 1.

To aim at Out (which address is 0x0001), sta ,X and stx ,X would require an X=0x01 but this is impossible (if the code takes the time to assign a value to X it wouldn't be able to compute the transition's value by time). Hence, we infer that the code's structure is:

start: ??? ???; 3 cycles; an instruction causing  $\bullet \leftarrow In$ st• Out; 4 cycles; an instruction causing  $Out \leftarrow \bullet$ ::;; other instructions

where  $\bullet$  stands for register A or register X. The only possible code fragments capable of doing so are:

	adc In	adc ,X	add In	add ,X	eor In	eor ,X
$I_1$	sta Out					
$I_2 \in$	lda In	lda ,X	ora In	ora ,X	ldx In	ldx ,X
	sta Out	sta Out	sta Out	sta Out	stx Out	stx Out

There is no way to further refine the analysis without more experiments, but one can already guarantee that as the execution of any of these fragments ends, the machine's state is either  $S_A = \{A = v_3, X = 0x00\}$  or  $S_X = \{A = 0x00, X = v_3\}$ .

Now assume that  $Out = v_3 = 0x10$ . Consider the code:

start:	ldx	In	;	3	cycles;	X←In		
	$\operatorname{stx}$	Out	;	4	cycles;	Out←X		
	lda	,Х	;	3	cycles;	[X]M→A	(instruction	$I_3$ )
	sta	Out	;	4	cycles;	Out←A	(instruction	$I_4$ )
	÷	:	;		;	other inst	cructions	

- Latch  $In \leftarrow v_4 = 0x02$ , reboot, wait fourteen cycles; witness the transition<sup>7</sup> 0x10  $\rightarrow$  0x02  $\rightarrow$  0xBE; power-off before the fifteenth cycle completes.
- Latch  $In \leftarrow v_6 = 0x04$ , reboot, wait fourteen cycles; witness the transition<sup>8</sup> 0xBE  $\rightarrow 0x06 \rightarrow 0xF6$ ; power-off before the fifteenth cycle completes.

As  $v_5 \neq \operatorname{dir}(v_4)$  and  $v_7 \neq \operatorname{dir}(v_6)$  the second transition is, again, necessarily caused by some member of the sta or stx families and, more specifically<sup>9</sup> one of the following:

<sup>&</sup>lt;sup>7</sup>  $v_5 = 0$ xBE is the opcode of 1dx, read from address 0x02

 $<sup>^8</sup>$   $v_7 = 0 \texttt{xF6}$  is the opcode of 1da ,X, read from address 0x06

 $<sup>^9</sup>$  taking timing constraints into account and ruling-out stx  $\tt,X$  who can only cause an  $\tt Out = 0x01,$  a value never witnessed.

$\mathtt{I}_4 \in$	sta Out	stx Out	sta ,X
--------------------	---------	---------	--------

 $I_3$  cannot be an instruction that has no effect on X and A as this will either inhibit a transition or cause a transition to zero (remember: immediately before the execution of  $I_3$  the machine's state is either  $S_A$  or  $S_X$ ). This rules-out eighteen jump instructions as well as all cmp, bit, cpx, tsta and tstx variants. lda *i* and ldx *i* are impossible as both would have forced 0x02 and 0x04 to transit to the same constant value.

In addition,  $v_5 \neq \operatorname{dir}(v_4)$  implies that  $I_3$  cannot be a dir-variant operating on A or X, which rules-out negx, nega, comx, coma, rorx, rora, rolx, rola, decx, deca, dec, incx, inca, clrx, clra, lsrx, lsra, lslx, lsla, aslx, asla, asrx and asra altogether.

As no carry was set, we sieve-out sbc and adc whose effects will be strictly identical to sub i and add i (dealt with below).

add i, sub i, eor i, and i and ora i are impossible as the system

$$\begin{cases} 0x02 \star x = 0xBE \\ 0x06 \star x = 0xF6 \end{cases}$$

has no solutions when operator  $\star$  is substituted by  $+, -, \oplus, \wedge$  or  $\vee$ . The only possible  $I_3$  candidates at this point are:

$$\texttt{I}_3 ~\in \texttt{sub} ~, \texttt{X} ~\texttt{and} ~, \texttt{X} ~\texttt{eor} ~, \texttt{X} ~\texttt{ora} ~, \texttt{X} ~\texttt{add} ~, \texttt{X} ~\texttt{lda} , \texttt{X} ~\texttt{ldx} ~, \texttt{X}$$

But before the execution of  $I_3$  the machine's state is:

$$S_{A} = \{A = 0x06, X = 0x00\}$$
 or  $S_{X} = \{A = 0x00, X = 0x06\}$ 

The ",X" versions of sub, and, eor, ora and add are impossible because:

– if the device is in state  $\mathcal{S}_A$  we note that

$$0x06 \star 0x06 \neq 0xF6 \text{ for } \star \in \{-, \lor, \oplus, \land +\}$$

– and if the device is in state  $\mathcal{S}_{X}$  we note that

$$\begin{array}{l} \mathsf{A} - \operatorname{opcode}(\mathtt{sub}, \mathtt{X}) = \mathtt{0}\mathtt{x}\mathtt{0} - \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{0} = \mathtt{0}\mathtt{x}\mathtt{1}\mathtt{0} \neq \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{6} \\ \mathsf{A} \wedge \operatorname{opcode}(\mathtt{and}, \mathtt{X}) = \mathtt{0}\mathtt{x}\mathtt{0}\mathtt{0} \wedge \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{4} = \mathtt{0}\mathtt{x}\mathtt{0}\mathtt{0} \neq \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{6} \\ \mathsf{A} \oplus \operatorname{opcode}(\mathtt{eor}, \mathtt{X}) = \mathtt{0}\mathtt{x}\mathtt{0} \oplus \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{8} = \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{8} \neq \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{6} \\ \mathsf{A} \lor \operatorname{opcode}(\mathtt{ora}, \mathtt{X}) = \mathtt{0}\mathtt{x}\mathtt{0} \lor \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{4} = \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{4} \neq \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{6} \\ \mathsf{A} + \operatorname{opcode}(\mathtt{a}\mathtt{d}, \mathtt{X}) = \mathtt{0}\mathtt{x}\mathtt{0} + \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{B} = \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{B} \neq \mathtt{0}\mathtt{x}\mathtt{F}\mathtt{6} \end{array}$$

ldx ,X is impossible as it would have caused a transition to opcode(ldx,X) =  $0xFE \neq 0xF6$  (if  $S_X$ ) or to 0x06 (if  $S_A$ ).

 $I_3$  is hence identified as being necessarily lda ,X.

It follows immediately that  $I_4 = sta$  Out and that the ten register-A-type candidates for  $\{I_1, I_2\}$  are inconsistent.

The phenotyped code is thus one of the following two:

Only the leftmost is capable of causing the observed transition  $0x02 \rightarrow 0xBE$ . All in all, we have built a *proof* that the device actually executed the fragment presented at the beginning of this section.

Extending the code further ahead to:

start:	ldx	In	;	X←In	0xBE	0x00
	stx	Out	;	Out←X	0xBF	0x01
print:	lda	,Х	;	A←M[X]	0xF6	
	sta	Out	;	Out←A	0xB7	0x01
	incx		;	$\mathtt{X} \gets \mathtt{X} + 1$	0x5C	
	bne	print	;	if $\mathtt{X}  eq 0$ goto print	0x26	OxFA

and subjecting the chip to three additional experiments, we observe:

Note that the identified code "happens to" allow the verifier to inspect with absolute certainty the platform's first 256 bytes. The rest is clear. The verifier does a last time measurement, allowing the Quine to print the device's first 256 bytes (power-off as soon as the last **bne** iteration completes, to avoid falling into the jaws of Aliens hiding beyond address **0x000B**).

It remains to check the Quine's payload (code between 0x000C and 0x00FF) and unleash the Quine's execution beyond address 0x000B. Quine won the game.

### 7 Questions

This work raises a number of intriguing questions: Is it possible to prove security using only space constraints? In the negative, can we modify the assembly language to allow such proofs<sup>10</sup>? Can space-constrained Quines solve spacecomplete problems to flood memory instead of receiving random data?

Another interesting challenge consists in developing a time-constrained Quine whose proof does not require rebooting but the observation of one long succession of transitions. We conjecture that such programs exist. A possible starting point might be a code (not necessarily located at start) similar to:

```
loop: sta
            Out
      lda
            In
      sta
            Out
      ldx
            In
      stx
            Out
      lda
            ,Х
            Out
      sta
      bne
            loop
```

Here the idea is that the verifier will feed the Quine with values chosen randomly in a specific set (to rule-out dir-variants) to repeatedly explore the code's immediate environment until some degree of certainty is acquired<sup>11</sup>.

If possible, this would have the advantage of making the Quine a *function* automatically insertable into any application whose code needs to be authenticated. Moreover, if we manage to constrain the capabilities of such a Quine, *e.g.* not allow it read data beyond a given offset<sup>12</sup>, we could offer the *selective* ability to audit critical program parts while preserving the privacy of others. For instance, the code of an accounting program could be audited while secret signature keys would provably remain out of the Quine's reach.

Finally, as time-constrained phenotyping is extremely quick (a few clock cycles), preserves nearly all the platform's data and requires only table lookups and comparisons, we currently try to extend the approach to more complex microprocessors and implement it between chips in motherboards.

<sup>10</sup> The approach would analogous to Java bytecode which is *purposely* shaped to fit type-inference.

<sup>&</sup>lt;sup>11</sup> To exit the **bne** loop the verifier will purposely read a zero somewhere.

 $<sup>^{12}</sup>$  e.g. the example above cannot read data beyond address 255
